Abstract. We present a *Chandra*-LETGS observation of the Seyfert 1 galaxy Mrk 279. This observation was carried out simultaneously with HST-STIS and FUSE, in the context of a multiwavelength study of this source. The *Chandra* pointings were spread over ten days for a total exposure time of ∼360 ks. The maximal continuum flux variation is of the order of 30%. The spectrum of Mrk 279 shows evidence of broad emission features, especially at the wavelength of the O VII triplet. We quantitatively explore the possibility that this emission is produced in the broad line region (BLR). We modeled the broad UV emission lines seen in the FUSE and HST-STIS spectra following the "locally optimally emitting cloud" approach. This method considers the emission from BLR as arising from "clouds" with a wide range of densities and distance from the source. We find that the X-ray lines luminosity derived from the best fit BLR model can match the X-ray features, suggesting that the gas producing the UV lines is sufficient to account also for the X-ray emission. The spectrum is absorbed by ionized gas whose total column density is $\sim 5 \times 10^{20}$ cm^{-2}. The absorption spectrum can be modeled by two distinct gas components (log$\xi \sim 0.47$ and 2.49, respectively) both showing a significant outflow velocity. However, the data allow also the presence of intermediate ionization components. The distribution of the column densities of such extra components as a function of the ionization parameter is not consistent with a continuous, power law-like, absorber, suggesting a complex structure for the gas outflow for Mrk 279.

Key words. Galaxies: individual: Mrk 279 – Galaxies: Seyfert – quasars: absorption lines – quasars: emission lines – X-rays: galaxies

1. Introduction

Active galactic nuclei (AGN) are believed to be powered by accretion into a super massive black hole (BH). Through the identification of narrow spectral features in the energy range $E < 2$ keV, the basic phenomenology of the absorbing ionized gas out-flowing from the vicinity of the BH has been established: approximately 60% of the Seyfert 1 galaxies display such an outflow (Crenshaw et al. 1999). Objects with an UV absorber always display an X-ray absorption component (Crenshaw et al. 1999; Kriss 2002). Recent results show that the absorber has to be a multi-ionization component gas and some of the components of the UV and X-ray outflow may be part of the same material (Gabel et al. 2005a). Only in the X-ray band higher ionized components, producing mostly He-like and H-like ions of C, N, O, and up to H-like iron, can be detected. These high ionization components have been reported to have a larger column density (e.g., Turner et al. 2005; Netzer et al. 2003) and sometimes a higher outflow velocity (e.g., Steenbrugge et al. 2005). The physical structure of the absorbing systems related to the BH activity is not understood. Independent measurement of the physical struc-

ture of the out-flowing ionized gas led to incompatible results. The density structure may be continuous as a function of the ionization level of the gas (NGC 5548, Kaastra et al. 2002, Steenbrugge et al. 2003). Alternatively, the absorber is clumped in discrete components, in pressure equilibrium surrounded by a hotter and tenuous phase (Krolik & Kriss 1995, 2001). The spectrum of NGC 3783 seems to be well described by this model (Krongold et al. 2003; Netzer et al. 2003). Finally, there are conflicting results on the spatial extent and the distance from the ionizing source of such an absorber. Behar et al. (2003), based on the XMM-*Newton* observation of NGC 3783, proposed that the out-flowing X-ray absorber has the same spatial distribution as the narrow line region (NLR) mapped in UV, as confirmed by the UV spectral analysis of this source (Gabel et al. 2005a). This picture would be analogous to the geometry drawn for the Seyfert 2 galaxies (e.g. NGC 1068, Kinkhabwala et al. (2002); Mrk 3, Sako et al. (2000)). Conversely, a *Chandra*-LETGS and HETGS study on NGC 5548 suggested that the outflow is more collimated with a small opening angle (Steenbrugge et al. 2005). The location of the warm absorbers may be as far as the NLR, or closer to the source, at ∼pc scale, where a molecular torus should exist (see Blustin et al. 2005, and references therein) or, finally, the ionized gas outflow may be generated by accretion disk instabilities (Proga 2003). The X-ray line emission spectrum turned out to be an important component in Seyfert 1 galaxies. Recombination lines, narrow and variable on long time scales are generally believed to arise in the NLR (e.g., Pounds et al. 2004). Moreover, broad emission features, several Å wide, have recently been detected in the X-ray spectra of some Seyfert galaxies. Whether some of them are due to curvatures of the primary continuum hiding absorption (Lee et al. 2001), or are relativistically broadened lines (Branduardi-Raymont et al. 2001; Sako et al. 2003; Ogle et al. 2004), is still unclear. The modeling of other detected broad excesses as broad lines or blends of lines, in the soft X-ray spectrum, points to emission from the BLR (Steenbrugge et al. 2005; Ogle et al. 2004). A deeper understanding of the physics behind such emission features is also important for a correct interpretation of the entire X-ray spectrum.

Mrk 279 is a Seyfert 1.5 galaxy, located at redshift $z = 0.0305$ (Scott et al. 2004). The source spectrum is affected by a relatively low Galactic absorption ($N_{\rm H} = 1.64 \times 10^{20}$ cm^{-2}, Elvis et al. 1989). Mrk 279 has been extensively studied by low resolution instruments (e.g., Weaver et al. 1995, 2001) mainly by virtue of the 6.4 keV iron emission line, which is characterized by a broad profile and a variable flux. The first systematic study on the soft X-ray energy band was carried out in 2002 using *Chandra*-HETGS, simultaneously with FUSE and HST-STIS (Scott et al. 2004). At that epoch both UV and X-ray observations show that the source was at the lower end of its historical flux range (Weaver et al. 2001). The $2 - 10$ keV flux was $\sim 1.2 \times 10^{-11}$ erg cm^{-2}s^{-1} and the 1000 Å flux was $\sim 0.13 \times 10^{-11}$ erg cm^{-2}s^{-1}Å^{-1}. While monitored by FUSE, the source became 7.5 times dimmer from 1999 to 2002 and a similar behavior was recorded in the optical (Bachev & Strigachev 2004). In the 2002 multiwavelength observation, a relatively short exposure time combined with a low flux state conspired against the detection of any significant absorption in the HETGS spectrum. The ionized absorber in Mrk 279 has indeed quite a low column density in the X-ray domain ($\rm N_H \sim 5 \times 10^{20} cm^{-2}$, this study), as compared for example to NGC 3783 ($\sim 3 \times 10^{22}$ cm^{-2}, Kaspi et al. 2001) or NGC 5548 ($\sim 5 \times 10^{21}$ cm^{-2}, Kaastra et al. 2002).

A large scale project has more recently focused on Mrk 279. The observations were carried out using HST-STIS, FUSE and *Chandra*-LETGS simultaneously. The methodology in studying the UV absorption is described in Gabel et al. (2005b, hereinafter G05), while Arav et al. (2005) focuses on the modeling of the structure of such absorber. For the LETGS data, the theoretical background for the line production from a meta-stable level of O V is described in Kaastra et al. (2004), while in the present paper we present the total modeling of the X-ray spectrum.

The X-ray flux we measure with *Chandra*-LETGS is $\sim 2.18 \times 10^{-11}$ erg cm^{-2}s^{-1} in the $2 - 10$ keV range, while the UV flux at 1000 Å is almost a factor of ten higher ($\sim 1.23 \times 10^{-11}$ erg cm^{-2}s^{-1}Å^{-1}, G05) than the 2002 UV observation. The flux history in the optical V band, recorded by the 0.9-m University of Nebraska telescope, shows that the source underwent a large flux rise during the ∼2 months preceding the present campaign (Gaskell et al. 2006, in prep.).

The paper is organized as follows. Sect. 2 is devoted to the analysis of the data and the modeling of the emission and absorption spectral features of Mrk 279. In Sect. 3 we discuss our results and in Sect. 4 we present our conclusions. The cosmological parameters used are: $\rm H_0$=70 km/s/Mpc, $\Omega_{\rm m}$=0.3, and Ω_Λ=0.7. The quoted errors refer to 84% confidence ($\Delta\chi^2 = 2$ for one interesting parameter), unless otherwise stated.

2. The data

Mrk 279 was observed seven times spread over ten days for a total duration of 360 ks, by the Low Energy Transmission Grating Spectrometer (LETGS, Brinkman et al. 2000) coupled with the HRC-S on board of *Chandra*. The nominal wavelength range in which LETGS operates is 1.7−150 Å, with an energy resolution of 0.05 Å. In Tab. 1 the observation log for Mrk 279 is shown. The data reduction was carried out using the standard CXC pipeline up to the creation of the level 1.5 event files. The steps leading to the final event file (level 2) follow the same line as CXC for the wavelength accuracy determination and effective area, only make use of an independent procedure, first described in Kaastra et al. (2002). Higher spectral orders have been taken into account in all spectral fitting, while they were subtracted, using a bootstrap method, from the "fluxed" spectrum (cts s^{-1} cm^{-2} Å^{-1}) uniquely for plotting purposes. The spectrum was differently re-binned, in channel space, depending on the features we wanted to focus on. A large re-binning (factor of 10) was used to model the continuum shape, while a binning of 2 was used for the study of the spectral features. In Fig. 1 (upper panel) the fluxed broad band spectrum is displayed, while the S/N of the unbinned spectrum is shown in the lower panel. We have a S/N of at least 5 for all wavelengths

between 2–58 Å, except for a small region around the instrumental C I edge near 40 Å. Over most of the 6–48 Å band, S/N is $\gtrsim 10$. This limit of S/N=10 is often seen as a necessary condition for reliable spectroscopy. The spectral analysis was carried out using the fitting package SPEX[1] (ver. 2.0).

2.1. Time variability

The light curve of Mrk 279 taken in the zeroth spectral order is shown in Fig. 2 where we mark also the epochs of the FUSE and HST pointings, during the multi-wavelength campaign. The count rate $c(t)$ of the X-ray data varies gradually, spanning the range between 0.49 c/s (during the minimum in observation 4) to 0.82 c/s (at the maximum of observations 5 and 7). No significant variations on time scales shorter than 10 ks are observed. Typical time scales $\mathrm{d}t/\mathrm{d}\ln c(t)$ for the more gradual variations are ∼120 ks. Details on the X-ray variability will be discussed elsewhere (Gaskell et al. 2006, in prep.).

2.2. Continuum spectrum

The continuum shape of the average spectrum is modeled by a power-law (average photon index $\Gamma = 2.01 \pm 0.01$), dominating at shorter wavelengths, and a “modified” black body emission with an average temperature $kT = 0.108 \pm 0.002\,\mathrm{keV}$, to account for a “soft excess” at longer wavelengths (18–80 Å, Tab.2). The black body model takes into account the modifications by coherent Compton scattering (see Kaastra & Barr 1989). The parameters of this fit are reported in Tab. 2. We have also fitted the spectrum of each of the seven observations using the same power law plus modified blackbody spectrum as used above for the combined spectrum. In Fig. 3 these continuum parameters are plotted in terms of percentage deviation from the value found for the combined spectrum, as a function of the observation number (and therefore of time, Fig. 2). We see that the power-law parameters agree within $\sim 2\sigma$ with the average value apart from two outlying points: the value of Γ for observation 5 and the $2-10$ keV luminosity for observation 4, to which the flux drop in the light curve is ascribed. The modified black body parameters are more stable over time, the maximum deviation being $\sim 2\sigma$ from the mean. The stable shape of the soft thermal component dominates the band where most of the absorption and emission spectral features are, while the power law dominates at 2–8 Å, where the spectral resolution starts to degrade, making the (few) spectral features at those short wavelength more difficult to study. The largely stable shape of the spectrum supports the assumption that the time-averaged continuum of the combined data can be used in our modeling of the absorption/emission components.

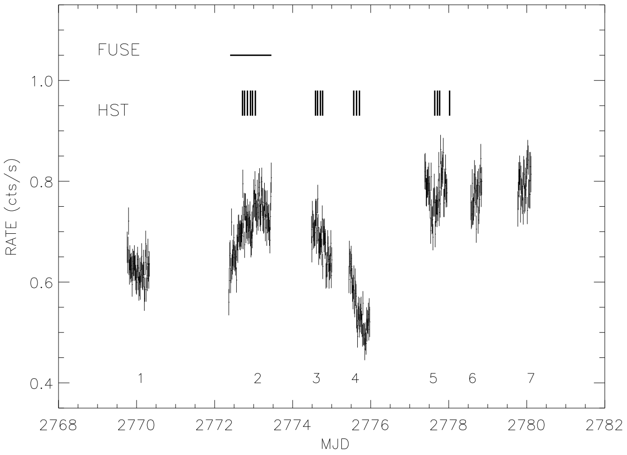

Fig. 2. LETGS light curve of Mrk 279 in the zeroth spectral order. Bin size: 1000 s. The individual 7 time segments are labeled at the bottom. The FUSE and HST pointings are also marked.

In the following we will describe first the modeling of the emission spectral features (broad and narrow). We will see how this is a necessary step in order to further describe the absorbed spectrum.

2.3. Emission lines

Residuals to the continuum model show many narrow absorption and emission features and also some broad excesses, roughly 1 Å wide, especially around the transitions of the

most prominent oxygen ions in the X-ray spectrum (O VII and O VIII). This can be seen, for instance, in Fig. 4, where the region around the O VII triplet is shown. We overplot the profile of a broad Gaussian line, only to guide the eye. Especially in this region, where any absorber is expected to show many (oxygen) features, the fitting of the absorption lines would be seriously compromised (e.g. O V and the O II Galactic absorption, Fig. 4) if these broad emission features are ignored. These excesses are present in all seven observations.

The uncertainty associated with the flux/shape of the broad X-ray lines is such that we would not be able to quantify if the broad excesses respond to the average flux variation of ∼25% experienced by the central source. Therefore we considered the whole data set.

2.3.1. A basic fit for the broad lines

We first attempted a purely phenomenological approach: we included broad Gaussian profiles, at the position of the main H-like and He-like ions of C, N, O to the continuum described in Sect. 2.2. The intrinsic flux of the lines is of course intercepted by the absorbers on the line of sight (Sect. 2.4), which must be consistently taken into account even in this simple modeling.

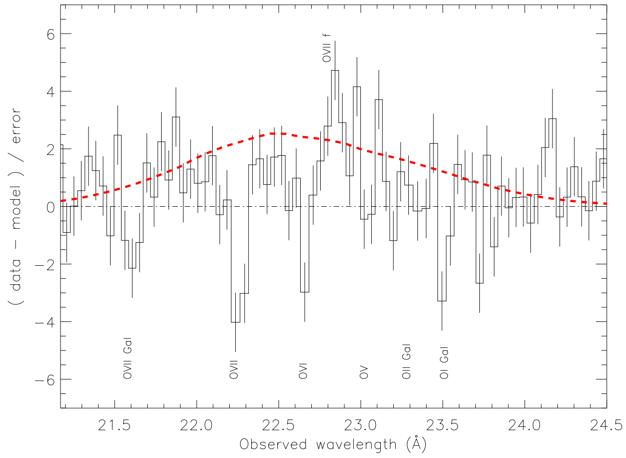

Fig. 4. Residuals, in terms of sigma, to the continuum model in the O VII triplet region. A broad Gaussian (dashed line) has been added only to guide the eye. The continuum is represented by a power law plus a modified black body absorbed by galactic absorption. The labels refer to the position of expected absorption/emission narrow lines.

The resulting unabsorbed profile of the lines is thus expected to be significantly modified with respect to that qualitatively drawn in Fig. 4. A contribution by narrow emission lines could be included only for O VII and O VIII, as they produce the only measurable narrow recombination lines (Sect. 2.3.3). For the O VII triplet we also formally included, beside the measured narrow forbidden line, the recombination and intercombination lines with flux $1/4$ of the forbidden line (assuming a purely photoionized gas with density $< 10^{9}$ cm^{-3}, Porquet & Dubau 2000).

The centroid of the broad Gaussian lines are kept fixed to the wavelength of the Lyα transition for C VI, N VII and O VIII. For the blended lines, the centroid was at first left free to vary in the range among the nominal lines' wavelength and later fixed to that value (Tab. 5). The width of the lines is a difficult parameter to determine. At this stage, we tentatively fixed the FWHM of the individual lines at ∼10000 km s^{-1}. The width for a triplet is therefore a blend of individual lines. For O VII we actually fitted the full-width-half-maximum (FWHM) of the blended triplet, keeping it fixed later on to evaluate the errors on the line luminosity. In Tab. 3 the result of this fit is shown. The intrinsic line luminosities listed in Tab. 3 are derived considering a self-consistent emission/absorption fit and the relative errors are evaluated from this best fit. In the last column we list the significance of each broad excess individually, in terms of $\Delta\chi^2$, starting from a model with no broad lines. $\Delta\nu$ is 1 (where ν is the number of degrees of freedom) as the width and the centroid of the line are kept fixed. With those constraints, we determine that the O VII triplet and the O VIII Lyα have a significant detection (approximatively 6 and 3 σ, respectively). Measuring the physical parameters, such as flux and FWHM, from this line-by-line fitting might be a quantitative way to model these excesses. However, given their relative weakness, this approach leads to severe uncertainties. First, the absorption lines that are

Table 3. Parameters of the X-ray broad lines from a line-by-line fitting. The line transition, its centroid (in Å), the FWHM in km s^{-1} and the rounded correspondent value in Å, the intrinsic line luminosity and the significance are listed (see text for details). Note that for the triplets the FWHM is the result of the blend of the lines.

Ion	wavelength Å	FWHM 10^4km s^{-1}	FWHM Å	Lum$_{\rm obs}$ (10^{41}erg s^{-1})	$\Delta\chi^2/\Delta\nu$

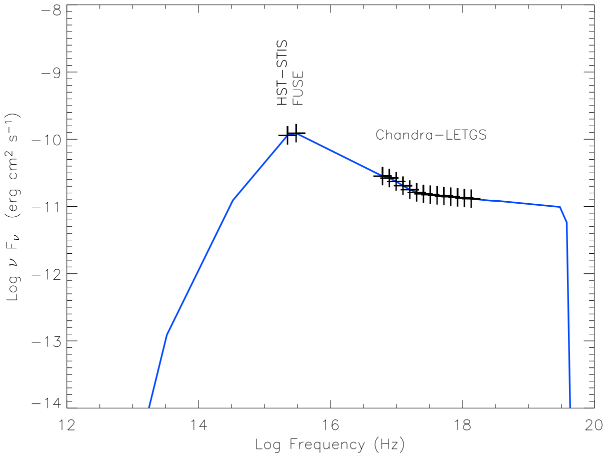

Fig. 5. The spectral energy distribution for Mrk 279. The points at 1000 and 1350 Å are the continuum flux of the simultaneous FUSE and HST-STIS observation, respectively. The X-ray continuum is taken from the present LETGS data.

superimposed on these profiles, the level of the continuum, and possible emission line blending, contribute to make the flux and width determination of these lines very uncertain. Second, the weaker lines, whose flux is only a few per cent higher than the continuum, can be easily missed.

2.3.2. A synthetic model for the broad lines: the LOC model

We looked for a physical model that would account for all the lines simultaneously. For instance, in analogy with the UV broad emission lines, one plausible possibility is that these emission features arise within the BLR. In order to self consistently test this idea, we first modeled the UV broad lines detected simultaneously by HST-STIS and FUSE. From the best fit synthetic model we then infer the X-ray line luminosities from the same emission-line gas to be compared with the LETGS data.

In the modeling, we considered the luminosity, corrected for the galaxy extinction (E(B-V)=0.016), of the broad component of the UV line profiles, listed in Tab. 4 (see also Fig. 1 of G05). The FWHM of the UV lines lie in the range $\sim 8500-9500\,{\rm km\,s^{-1}}$. A full description of the UV data analysis of the broad lines will be described in Scott et al. (2006, in prep.). We used Cloudy (Ferland 2004), ver. 95.06, to reproduce the UV emission from the BLR. The spectral energy distribution (SED) of the incident continuum that we used is shown in Fig. 5. The UV points at 1000 and 1350 Å come from the FUSE and HST-STIS measurements, respectively (G05), while the X-ray ionizing continuum comes from the time averaged LETGS data. Lacking any information of the high energy spectrum, we artificially cut off the X-ray power law at ∼150 keV. The low energy part of the SED resembles the shape assumed for the standard photoionizing continuum used in Cloudy[2]. We kept the luminosity of the ionizing radiation fixed: $\log L = 44.57$ erg s^{-1}, between 1 and 1000 Rydberg, as measured from the SED.

In order to reproduce emission from a large range of ionization stages, we followed the "locally optimally emitting clouds" prescription (LOC, Baldwin et al. 1995). For this purpose, we created a grid of values for the density n and the distance r of the BLR clouds. Once these parameters are set, the ionization parameter is readily calculated: ξ=L/nr^2. We computed the integrated luminosity of the lines, weighted by a power law distribution of the density n and the distance r and assuming spherical symmetry (Baldwin et al. 1995):

$$L_{\rm line} \propto \int\int L(r,n)\; r^{\gamma}\; n^{\beta}\; dr\; dn. \tag{1}$$

The β parameter was fixed to -1 (e.g. Korista & Goad 2000), while the slope of r, γ, was a free parameter in the fit. The density n ranged between $\sim10^{8-12.5}$ cm^{-3} with a step of 0.125 in log. The same step was taken for the radius, which ranged between $10^{14.7-18}$ cm. Densities lower than $n = 10^8\,{\rm cm^{-3}}$ are not expected within the BLR, while for densities $n = 10^{13-14}\,{\rm cm^{-3}}$ the cloud emission would be, in most cases, continuum rather than lines (Korista et al. 1997). The wide range of distances allows us to completely follow the luminosity distribution of the main X-ray lines as a function of radius. The gas located at distances $\lesssim 10^{15.3}$ cm gives, for all lines, a minor contribution to the integrated luminosity. The column density was fixed to 10^{23} cm^{-2}, as most of the emission should occur for $N_{\rm H} = 10^{22-23}\,{\rm cm^{-2}}$. Since in the observed line luminosity a main reason of uncertainty is, at all wavelengths, line blending, to bypass the line-blending problem, the lines predicted by Cloudy for each n and r, which could be a result of a blend, were summed up (Tab. 4). The best fit was reached through a χ^2 minimization.

In Fig 6 (upper panel), the data and our best fit are displayed for the FUSE and HST-STIS lines (listed also in Tab. 4). The model seems to describe the broad line average emission reasonably well if $\gamma = -1.02 \pm 0.14$ (this is the 84% confidence level for one interesting parameter). The value of γ is the only fitting parameter. The integrated covering factor of the clouds set, evaluated only on the basis of the fitting of the hydrogen Lyα normalization, is 34±26%. Another parameter that was not fine-tuned in the fit is the outer radius of the BLR. The residuals to the best fit model are shown in Fig. 6 (lower panel). Within $\sim 2\sigma$ the observed line luminosities agree with the LOC model.

---

[2] ftp://gradj.pa.uky.edu/gary/cloudy_gold/docs/hazy1_06_01_rc1.pdf

Other complicating factors are likely to contribute to the observed BLR emission line spectrum. For example, the abundances may be different than solar, the line emitting clouds may have a wider range of column densities, or the geometry of the system maybe different than the simple spherical symmetry assumed here. However here we seek a simple parameterization that explains the bulk of the BLR emission. A detailed model of the UV lines produced by the BLR would be beyond the scope of this paper.

The luminosities of the major X-ray lines, as predicted by the BLR model are listed in Tab. 5. In this table, the luminosity of the Gaussian profiles with which the LETGS spectrum was fitted without using a synthetic model are listed again, for comparison. We stress that these lines were not included in the LOC model, which was based instead on the UV data only. This choice was made to minimize possible errors that a fit based on the X-ray data (complicated by the continuum level and the absorption lines) would have brought to the LOC model fitting. The luminosities predicted by the LOC model are consistent, within the errors, with a crude line by line fitting. In Fig. 7 the best fit radial profile of the intrinsic line luminosity, integrated along the density (n^{-1}) is displayed for eight interesting ions. The diamond points locate the luminosity-weighted mean radius (e.g. Bottorff et al. 2002):

$$R_{\rm lw} \propto \frac{\int\int L(r,n)\; r^{\gamma+1}\; n^{\beta}\; dr\; dn}{\int\int L(r,n)\; r^{\gamma}\; n^{\beta}\; dr\; dn}. \tag{2}$$

In the figure, the relevant X-ray ions are included along with O VI, which lies in the FUSE bandpass, and C IV, N V and H Lyα, observed by HST-STIS. Most of the predicted luminosity should arise from clouds located at $r \sim 10^{16.3-17.5}$ cm. The UV ions seem to be confined to radii $r > 10^{17}$ cm, while not unexpectedly, the mean emitting radius for the X-ray lines would lie 10 times further in. Extrapolating the model, we see that in principle the X-ray lines, in contrast to most UV ions, have a non negligible luminosity tail from radii smaller than 10^{16} cm.

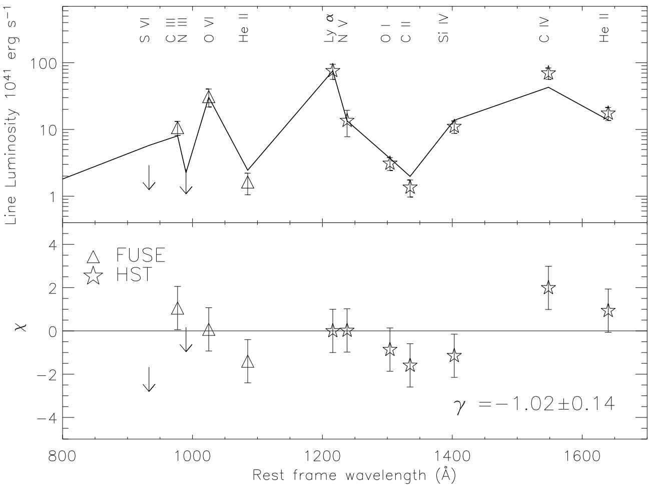

Fig. 6. Best fit of the intrinsic luminosity of the UV broad emission lines (upper panel). The model is displayed by a continuous line only to guide the eye. Lower panel: residuals in terms of σ to the best fit.

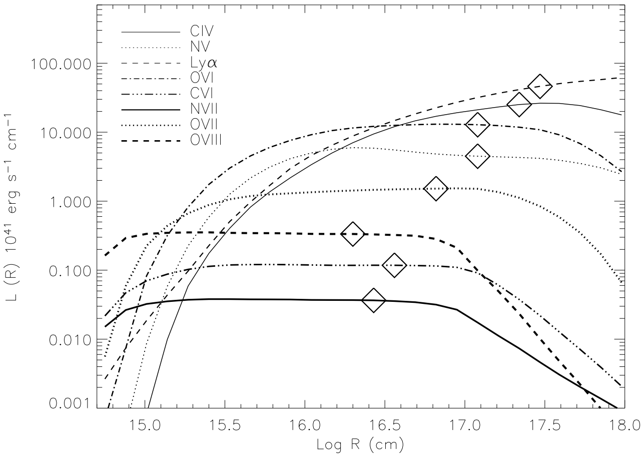

Fig. 7. Best fit luminosity profiles of eight of the ions considered for the fit. The luminosity was integrated at each radius using the weighting function n^{β}. For each emission line the diamonds indicate the luminosity-weighted radius. Note that the model underpredicts the observed luminosity of C IV by ∼40%.

Based on these results, we included in the final X-ray spectral fit six Gaussian profiles with luminosity fixed at the value predicted by the LOC model. The widths of the individual lines were set to the maximal value found in the UV (FWHM=9500 km s^{-1}), very similar to the value used in the line-by-line fit (Sect. 2.3.1). For the triplets, the blend of the three lines set the total FWHM. For O VII, we used instead the same FWHM as determined in the phenomenological fit (Tab. 3). The wavelengths were left free to adjust in a range of ±0.2Å around the centroid of the main line, mainly to take into account the line blending for triplets. The modeled line profiles are shown in the lower panel of Fig. 8. The following analysis on the absorption spectrum was performed after the inclusion of the broad emission lines as predicted by the LOC model.

2.3.3. Narrow emission lines and RRCs

Narrow emission features are not a dominant component of the total spectrum of Mrk 279. The flux of the O VII forbidden line and the O VIII Lyα are $1.0 \pm 0.6 \times 10^{-14}$ and $7 \pm 5 \times 10^{-15}$ erg cm^{-2} s^{-1}, respectively. Finally, the flux of the O VII Heβ line is $4 \pm 3 \times 10^{-15}$ erg cm^{-2} s^{-1}. Carbon recombination lines

Table 4. Rest wavelength, along with the observed luminosity and the luminosity predicted by the LOC model of the broad UV lines as measured by FUSE (labeled 1) and HST-STIS (labeled 2). For each observed blended-line, the value of $\mathrm{Lum}_{\mathrm{LOC}}$ consistently refers to the summed contribution of the lines in the blend.

Ion	Wavelength (Å)	$\mathrm{Lum}_{\mathrm{obs}}$ (10^{41} erg s^{-1})	$\mathrm{Lum}_{\mathrm{LOC}}$ (10^{41} erg s^{-1})	Inst	Notes
S VI	$933 + 944$	<2.9	5.7	1	
C III	977	10.7±2.5	68.0	1	
N III	989+991	<2.52	2.2	1	
Lyβ + O VI	$1025 + 1032 + 1038$	31±6	30.4	1	
He II	1085	1.6±0.6	2.4	1	
Lyα	1216	75.7±19.4	75.7	2	1
N V	$1238 + 1242$	13.6±6.0	13.4	2	
O I +Si II	1304	3.1±0.6	3.7	2	
C II	1335	1.3±0.4	2.0	2

C IV	$1548 + 1551$	70±12	42.9	2	
He II	1640	17±4	13.8	2	3

Notes: (1) Blended with O V] (1218 Å) and He II (1216 Å), (2) blended also with the O IV] quintuplet (1402 Å) and the S IV] quintuplet (1406 Å), (3) blended with the O III] doublet (1661+1666 Å).

Table 5. Rest wavelengths and intrinsic luminosity (in units of 10^{41} erg s^{-1}) of the lines in the LETGS (as reported in Tab. 3) compared with the X-ray line luminosities as predicted by the LOC model (last column) are listed. Note that the observed X-ray line luminosities were not used in the LOC fitting, which was based on UV data only. Here the triplets location has been identified with the wavelength of the forbidden line.

Ion	Wavelength (Å)	$\mathrm{Lum}_{\mathrm{obs}}$ (10^{41} erg s^{-1})	$\mathrm{Lum}_{\mathrm{LOC}}$ (10^{41} erg s^{-1})
C V[1]	41.47	< 3	0.3

are not visible in the total spectrum. Radiative recombination continua (RRCs) of C V and C VI (at λ_{obs}=32.57 and 26.05 Å, respectively, Fig. 8) are also seen. The temperature of the C V RRC is $kT = 1.7^{+1.0}_{-0.5}$ eV, with an emission measure $EM = 2.7 \pm 2 \times 10^{61}$ cm^{-3}. For the C VI RRC, $EM < 1.5 \times 10^{61}$ cm^{-3}, fixing the temperature at the C V value.

2.4. The absorbed spectrum

The LETGS spectrum shows absorption lines, at the redshift of the source, over the $\sim 5 - 45$ Å band, indicating that a gas with a range of ionization stages must be present. In Tab. 6 we list these lines, reporting the theoretical wavelength and the measured equivalent width (EW). The H-like and He-like ions of C, N and O are generally well determined. We report also the formal equivalent widths for several important diagnostic lines that are not significantly detected. These measurements help constraining column densities and the determination of the global properties of the absorber. The inferred velocity dispersions are affected by large errors for most of the ions considered. Therefore we took into account only the strongest ions: O VII, O VI, C VI and C V to calculate a mean velocity dispersion $\sigma = 46 \pm 21$ km s^{-1}, using a curve of growth method. This value is in rough agreement with FUV values as measured by FUSE (G05). The velocity dispersion found for FUV absorption lines is 50 km s^{-1}. This is the value we adopt in the modeling.

For the lines whose EW is better determined, we fitted also the blue-shift with respect to the laboratory wavelength (Tab. 6). The uncertainty on the blue-shift is proportional to $\Delta v/(\mathrm{S/N})$ where Δv is the velocity resolution at a given wavelength and S/N is the signal-to-noise ratio of the detected feature. For the lines located at longer wavelength, the shift measurement is in principle more precise. However, the higher resolution in these regions is compensated by a lower S/N ratio. Deriving the covering factor of the ionized absorbing gas from the X-ray data

Table 6. Laboratory wavelength, formal EW and outflow velocity for the X-ray absorption lines. The EW and the column densities predicted by models M1 and M2 assume different covering factors for the absorbing gas and are discussed in the text.

is a difficult task, due to the insufficient energy resolution. The most simple case is to assume a covering factor of one. The result of this fit is shown in Tab. 6 (model M1) where the EW and the column density of the most prominent lines are listed. The fitting was performed using the SLAB model in SPEX, which calculates the transmission through a thin layer of gas, making no assumption on the underlying ionization balance (Kaastra et al. 2002). In this model the tunable parameters are: the individual ionic column densities, the width of the lines, the outflow velocity and the covering factor. However, for this observation of Mrk 279, additional information is provided by the simultaneous UV data. In particular, the UV absorber for Mrk 279 shows evidence of two velocity components (indistinguishable with the X-ray resolution) whose covering factor differs from unity by 10% and 7% respectively. Here we test this model using the LETGS data. The model M2 in Tab. 6 assumes two components (i.e. two SLAB components), as found from the FUSE analysis (G05). In the first component, the velocity dispersion is set to σ=50 km s^{-1} with an assumed covering factor of 0.9. The second component contains 4% of the column density of the first component, the velocity dispersion is 28 km s^{-1} and the covering factor is 0.93. The predicted EW and the derived column densities for the two models are compared in the table. With the present LETGS data we are not able to distinguish between the two approaches (M1 and M2) and the X-ray absorber is consistent to cover all the line of sight. This is reasonable, as the X-ray source may be smaller than the UV source such that the ionized gas sees it as point-like. For simplicity we will assume that the X-ray gas has a covering factor of one.

In the following, we describe two viable models to physically describe the ionized absorption in Mrk 279: separate gas

components differing in ionization parameter, column density and outflow velocity (Sect. 2.4.1) and a continuous column density distribution as a function of the ionization parameter (Sect. 2.4.2).

2.4.1. A two ionization components model

We modeled the data in terms of physical warm absorber components. For this purpose, we used the XABS model in SPEX. From an input spectral energy distribution (Fig. 5) for the ionizing continuum of the source, the model interpolates over a large grid of values for ξ and $N_{\rm H}$, pre-calculated using Cloudy. Abundances are assumed to be solar (Grevesse & Sauval 1998). The data require at least two ionized absorbers located at the redshift of the source. In Tab. 7 we list the hydrogen column density, the ionization parameters and the outflow velocity of the absorbing gas. The best fit obtained with this model is displayed in the lower panel of Fig. 8. In the upper panel the transmitted spectrum is displayed. The light solid line refers to the lower ionization absorber while the higher ionization gas is highlighted with a dark solid line. The low ionization absorber (component 1 in Tab. 7) is characterized by a ionization parameter $\log\xi \sim 0.47$ and it is tightly determined by the fit of the strong absorption lines of C V, C VI, N VI, O VI and O VII (Fig. 8). The other component (labeled 2 in Tab. 7) is slightly faster and more ionized ($\log\xi \sim 2.49$). It is mainly marked by the O VIII line, but also other high ionization absorption lines, detected with a lower significance, like Fe XVII-Fe XIX, Ne IX, Ne X Mg XI and Si XIII, help in defining the parameters of this second component. Adding a second component improves the fit by $\Delta\chi^2/\Delta\nu = 40/2$, corresponding to a significance > 99.5%. Many of the lines of the high ionization system lie in a region with a lower velocity resolution ($\Delta v \sim 750$ km s^{-1} at 20 Å) and the determination of the physical parameters is therefore affected by higher uncertainties. However, if only the $\xi = 0.47$ absorber is considered, the O VIII Lyα line is poorly fitted (Fig. 9). Finally, as seen in Tab. 6, O VIII and O V have comparable column densities (the ratio is ~2) and this cannot be reached with a single ionization parameter. The column density of the two ionization components is quite low: 1.23 and $3.2{\times}10^{20}$ cm^{-2} for $\log\xi = 0.47$ and $\log\xi = 2.49$, respectively.

Table 7. The two absorption components at the redshift of Mrk 279. For each component we list the value of the ionization parameter $\log\xi$, the column density $N_{\rm H}$ and the outflow velocity $v_{\rm out}$.

	$\log\xi$ erg s cm^{-1}	$N_{\rm H}$ 10^{20}cm^{-2}	$v_{\rm out}$ km s^{-1}
1	0.47 ± 0.07	1.23 ± 0.23	-202 ± 50
2	2.49 ± 0.07	3.2 ± 0.8	-560 ± 130

2.4.2. Continuous distribution model

Alternatively to a discrete-components fit, the absorbed spectra can be modeled also as a continuous distribution of the hydrogen column densities of the ionized medium as a function of the ionization parameter. This is achieved using the WARM model in SPEX. The spectrum is fitted by a series of XABS models at intervals of 0.2 in $\log\xi$. At desired values of $\log\xi$, the error on the corresponding hydrogen column density ($N_{\rm H}^{\rm warm}$) is evaluated. We chose a $\log\xi$ interval between -1 and 3.2 and we evaluated $N_{\rm H}^{\rm warm}$ at those 2 points plus 2 points, equally spaced, in

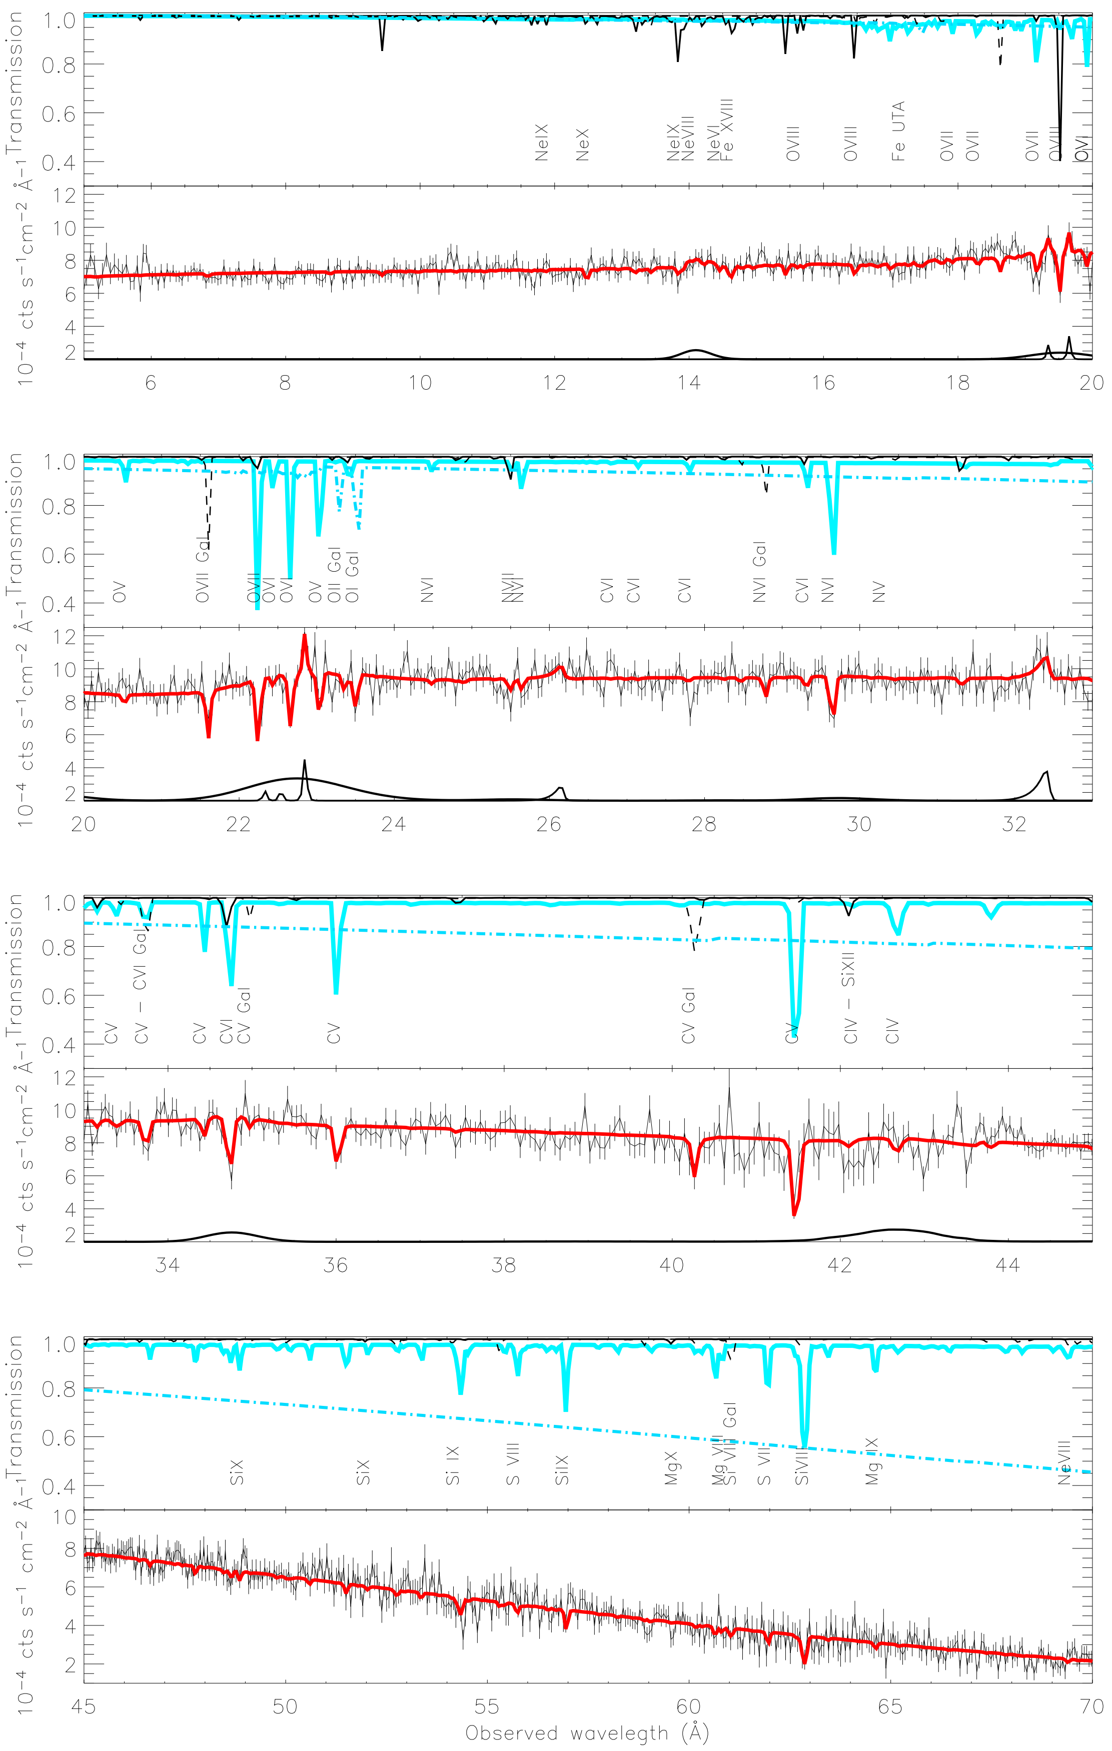

Fig. 8. Lower panel: best fit to the LETGS spectrum of Mrk 279 divided per wavelength range. The broad emission, predicted by the LOC fitting, and the narrow emission features, shifted up of a factor 2 for plotting purpose, are also overplotted. Upper panel:

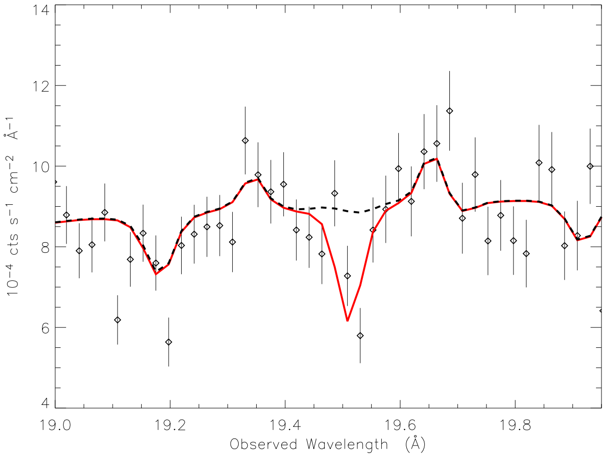

Fig. 9. Detail of the O VIII absorption line, fitted with only one component ($\log \xi = 0.47$, dashed line) and with two components ($\log \xi = 0.47, 2.49$, solid line).

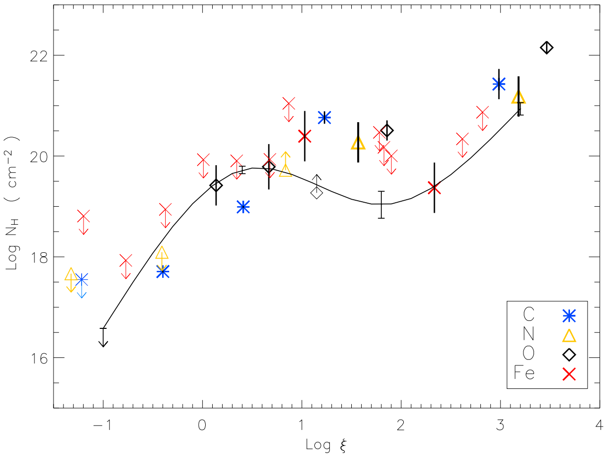

Fig. 10. The hydrogen column density as a function of the ionization parameter determined for: single ions (individual points) and an $N_{\rm H}$ continuous distribution model (solid line). See Sect. 2.4.2 for a full description.

between. These four points (at $\log \xi = -1, 0.4, 1.8$ and 3.2, respectively), smoothly connected by the finer grid of $N_{\rm H}$, determined by the XABS series, are plotted in Fig.10 as a solid thick line. Superimposed to that, we plot the derived hydrogen column density for the more abundant elements: carbon, oxygen, nitrogen and iron. These column densities are again inferred using the SLAB model. The equivalent hydrogen column densities for each ion are then derived using solar abundances. For this fit we left out the energies above 6 keV. In that region many K-shell transitions of iron ions are present, but due to the low effective area and possible calibration uncertainty the column density of important ions as Fe XXIII-Fe XXIV would have been wrongly evaluated. Moreover, low ionization ions of carbon (C I-C IV) and nitrogen (N I-N V) are not well determined, as their only feature in the X-ray band is the K edge. At the typical column density of the warm absorber of Mrk 279, the edge optical depths of those ions is of the order of $10^{-(3-4)}$ only. Therefore, we chose not to include these ions in the SLAB fit. For the column density of C II, C III, N II and N III, we used the values reported in Scott et al. (2004). The ionic column density of C IV, N V as well as O VI could be taken from the simultaneous UV data (G05). In Fig. 10, the hydrogen column density derived from the ionic concentrations for each ion is plotted against the $\log \xi$ values at which the ion is most likely formed. In particular, the $\log \xi$ value for each specific ion i is the result of an integration over large grid of $\log \xi$ values ($-8.5 - 6.5$) vs ionic column density (Steenbrugge et al. 2005). For many ions the column density cannot be determined with accuracy and there is a large scatter in the values. At $\log \xi$ in the range $0 - 1$, the WARM synthetic model is well traced by the single ions of O V-O VI. While the line for $\log \xi$ between 2.5 and 3 is represented mainly by the iron ions (Fe XIX-Fe XX) and by the H-like ions of N and C. Carbon ions suffer from a high uncertainty, as some of them lie close to the deep C I instrumental edge. The two approaches that we described above do not deliver the same physical picture. This will be discussed in Sect. 3.2.

2.4.3. Short-term variability in the warm absorber

So far we have studied the combined spectrum of Mrk 279. A short term variability in the warm absorber in response to the modest continuum changes can in principle be detected. However, the analysis of the imprint of the warm absorber, separately for the seven data sets, did not provide evidence of a statistically significant change. In Fig. 11 we show, as an example, the comparison between the spectra taken during the 4th and 5th time intervals, when the source underwent a major flux change, on a time scale of 2-3 days (Fig. 2). The 4th spectrum has been normalized by the higher flux unabsorbed continuum of the 5th observation. In this way any spectral modulation caused by a continuum change in flux and/or shape is canceled out and only the information on the absorbers remain. In the continuum also broad lines are included, as they are essential components in the evaluation of narrow absorption features. We see that the oxygen complex does not change significantly. The iron UTA region ($\sim 15 - 18$ Å, observed wavelength) is a useful tool to detect variations of the warm absorber (e.g, Behar et al. 2001; Behar et al. 2003; Krongold et al. 2003) as a small variation of the ionization parameter of the gas would shift the iron UTA on the wavelength axis. No significant shift is detected in the data.

2.4.4. Absorption at redshift zero

The spectrum of Mrk 279 is also marked by narrow absorption lines which are consistent with being produced at zero redshift. Weakly ionized absorption, likely to arise in the ISM of our Galaxy is highlighted by the O I feature at 23.04 Å and a weaker O II absorption line (Fig. 8). Such an absorption is well parameterized by a collisionally ionized gas with

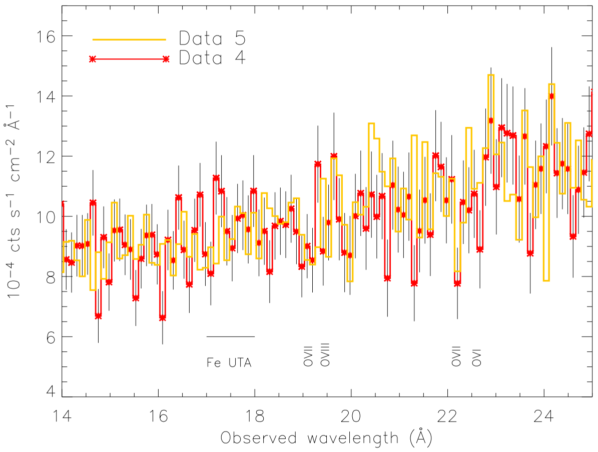

Fig. 11. Comparison between the 4th and the 5th segment of Mrk 279 observation (Fig. 2). The 4th spectrum (continuum line with asterisks) is normalized to the unabsorbed continuum of the 5th observation. The 5th spectrum is plotted with the light-solid line.

a very low temperature (3.1 ± 1.2 eV) and a column density of $0.72 \pm 0.08 \times 10^{20} \mathrm{cm}^{-2}$. This source is already known to show an ionized absorber at redshift zero (traced by O VI in the UV band, e.g. Savage et al. 2003). Also in the X-ray band we detect ionized material traced by several absorption features from O VII, N VI, C V and C VI (Fig. 8). We modeled this system of lines with a collisionally ionized plasma model with a temperature $kT = 7.2 \pm 1.7$ eV and a column density $N_{\mathrm{H}} = 3.6 \pm 0.3 \times 10^{19}$ cm^{-2}.

This absorbing gas may be located in the environment of the Milky Way (e.g., Sembach et al. 2003; Wang et al. 2005), in the form of high velocity clouds moving and interacting with each other in the Galactic halo (Collins et al. 2005). Another interpretation locates the absorbing gas on 1–3 Mpc scale, in the local group (Nicastro et al. 2002). A study of the O VI absorption line in the Mrk 279 UV spectrum is presented by Fox et al. (2004). A detailed interpretation of the X-ray absorbing components on the line of sight of Mrk 279 is discussed e.g. in Williams et al. (2006).

3. Discussion

3.1. Emission from the broad line region

The broad emission features detected in the LETGS spectrum of Mrk 279 can be modeled in terms of emission lines from the BLR. Using the LOC model (Baldwin et al. 1995), we found that the UV lines are modeled by emission from clouds whose density and radial distribution follow a power law. The radial distribution is found to decrease with a slope $\gamma = -1.02 \pm 0.14$, while the slope for the density distribution was fixed to -1 (Sect. 2.3.2). The integrated covering fraction of the clouds set, calibrated on the hydrogen Lyα fitting, is loosely constrained, being 34±26%. These results are in agreement with what found for the composite quasar spectra (Baldwin 1997). The LOC model was also applied to another bright Seyfert 1 galaxy, NGC 5548, (Korista & Goad 2000). In that case, the density and radial distributions slopes $\beta = -1$, $\gamma \sim -1.2$, respectively, well explained the HST-STIS data. In the present paper for the first time the LOC model has been extended to the X-ray band. The intrinsic luminosity of the X-ray lines have been calculated from this model and applied to the LETGS data fitting. An independent fit of the X-ray spectrum using Gaussian profiles leads to flux estimates which are consistent, within the errors, with the ones predicted by the LOC (Tab. 5), strengthening the validity of this approach. In the case of Mrk 279, the O VII triplet complex is the most prominent feature (30% above the continuum, Fig. 8), as this oxygen ion is steadily produced in a wide range of physical conditions. The other broad X-ray lines are weaker (∼10% above the continuum), but help in modifying the continuum and better constrain the warm absorber parameters. For these lines we cannot draw firm conclusions, as their significance in the data is relatively low.

It is feasible that there may be a part of the BLR which has higher ionization and that produces lines only visible in the X-ray band. This may give rise to some additional flux in the lines, possibly variable in time and thus appearing only in some time segments, but its level is within the noise. In principle, measuring the amount of the excess would allow us to quantify the physical parameters of a highly ionized skin of the BLR. However it is extremely challenging, first because of the relatively low statistical significance of any additional excess, second because we modeled the BLR using an average source flux that possibly introduces some more scatter in the predicted values of the X-ray lines luminosity. Being able to study a part of the BLR which only emits in the X-ray band would be indeed very important in understanding the stratification of the BLR and its velocity field (e.g., Baldwin 1997; Gonçalves et al. 2001). Following further the BLR interpretation, we find that the luminosity–weighted radii (Sect. 2.3.2) map a wide region that extends from 10 to 100 ld from the central source, which produces lines visible both in UV and X-ray band. This size is smaller (∼67 ld) when only the UV lines are considered. This estimate is larger than the BLR size obtained by reverberation mapping studies ($<$ 30 ld, Stirpe et al. 1994, and references therein). However, we note that the ionization conditions within such an extended region are sensitive to the long-term flux history of the source. In particular there is evidence that more than forty days before the present multiwavelength campaign, the V-band flux of Mrk 279 was up to a factor of 8 lower (depending on the host galaxy subtraction, Gaskell et al. 2006, in prep.). From that epoch, the V band flux, which should be, on long time scales, correlated also with the high energy flux, gradually rose to reach the higher state caught by LETGS-FUSE-HST. As the size of the BLR is proportional to the square root of the ionizing luminosity (Peterson 1993), the size estimated here could be reduced by a factor as large as two or three.

The luminosity-weighted radius of the higher ionization X-ray ions is located at radii up to ten times smaller than for the UV ions. If the motion of the BLR clouds is purely keplerian, this would imply a velocity broadening up to a factor of three larger. The only broad excess for which we measured the FWHM is the O VII triplet blend (FWHM=$1.9^{+0.7}_{-0.4} \times 10^4$ km s^{-1}, Tab. 3) which is consistent, within the errors, with such a large broadening. Unfortunately in this data set this possibility cannot be tested on non-blended, higher ionization lines (like for instance C VI). The extrapolation of the BLR model down to small radii shows that the emission of the X-ray BLR has a non-negligible tail that goes down to $\sim$0.8 ld from the source, corresponding nominally to $\sim$300 Schwarzschild radii, given the BH mass of Mrk 279 ($\sim 3 \times 10^7 M_\odot$, Wandel et al. 1999). At this specific distance we would not expect a significant relativistic broadening of the line profile, but X-ray emission from highly ionized gas that is not efficiently producing UV lines would be possible (Fig. 7).

The detection of relativistically broadened line profiles at soft X-ray energy has been claimed for a number of sources (e.g. Branduardi-Raymont et al. 2001; Kaastra et al. 2002; Ogle et al. 2004). Our LETGS data do not show significant evidence of an asymmetric profile, especially at the wavelength of O VIII, N VII, C VI. Moreover, these profiles would be blurred by the wide, non-relativistic lines produced in the BLR. Among the H-like lines that we are able to detect in the LETGS band, O VIII lies in a privileged region, where the effective area is higher and the spectrum is not contaminated by instrumental features. However, to model a skewed, relativistically broadened, profile for O VIII is difficult because of the absorption features of the iron UTA at observed wavelength of $\sim$ 17 Å for the warm absorbers intrinsic to Mrk 279, and at $\sim$ 19 Å for the ionized absorbers in our Galaxy. The structure of the iron UTA may not be yet completely accounted for in the models and may cause additional uncertainties.

3.2. The structure of the warm absorber

The spectrum of Mrk 279 is absorbed by at least two absorption systems (Sect. 2.4.1). They show a significant blue-shift and a relatively high value of the ionization parameter and therefore can be unmistakably associated with the warm absorber seen in other Seyfert 1 galaxies (Tab. 7). Low ionization metals (e.g. C II, C III, N II) are marginally detected in the UV band, but for completeness, we included them in our analysis (Sect. 2.4.2). As discussed in Scott et al. (2004), the association of these ions with the nuclear activity is unlikely. Because of their low ionization and the lack of any blue-shift in the lines, they most probably arise in the Mrk 279 host galaxy. The two high ionization components may be the only discrete constituents of the warm absorber (e.g. Krongold et al. 2005) or be only a part of a multi-ionization, continuous outflow (Steenbrugge et al. 2005). A discrete-components scenario would be supported by finding that the observed components values have the same $\log \Xi$ in the curve of thermal stability, which is shown in Fig. 12. Here we plot the log-log distribution of the pressure ionization parameter (Ξ) *vs* the electronic temperature (T) for Mrk 279. The value of Ξ is defined as: $\Xi = L/4\pi r^2 cp$, that is the ratio of photon pressure to gas pressure. This may also be expressed as a function of ξ and the electronic temperature T: $\Xi = \xi/4\pi ckT$. The curve was obtained using Cloudy, calculating a grid of values of logξ and the relative electronic temperature of a thin layer of absorbing gas illuminated by an ionizing continuum. The shape of the curve is sensitive to the SED of the source (Fig.5). The filled squares in Fig. 12 correspond to the logΞ values for the warm absorbers detected in Mrk 279. Given their position on the S curve, these component cannot share the same pressure ionization parameter. This would have ensured a long-lived structure for a discrete-component warm absorber unless other mechanisms, like magnetic confinement, are playing a role. If this were case, pressure equilibrium would not be mandatory. Also a high amplitude variability of the warm absorber in response to a continuum flux variation could be in favor of a discrete-component model (e.g., Krongold et al. 2005). Observationally, a small variation of the ionization parameter would cause a detectable shift in the iron M shell UTA complex. In the case of Mrk 279 this possibility cannot be tested, as the variation of the source is too small and the warm absorber too shallow to be able to detect a shift in the iron region (Fig. 11).

On the other hand, also a scenario that considers a continuous distribution over ξ (Sect. 2.4.2) cannot be straightforwardly proven. In Fig. 10 we showed the results of the WARM model, which mimics a continuous $N_{\rm H}$ distribution (Sect. 2.4.1). We see that the hydrogen column density distribution derived from single ions appears to give a different picture of a power law-like distribution. Indeed, if we take into account only the higher ionization ions ($\log \xi > 0$), taking out all the upper limits from the fit, the data can be modeled by a power law with index $\alpha \sim 0.49$, where we consider $N_{\rm H} \propto \xi^\alpha$. This is very similar to what was found for NGC 5548, where Steenbrugge et al. (2005) estimated $\alpha \sim 0.40$ for this range of ionization parameters ($\log \xi \sim -0.2 - 3.5$), despite that the column densities for the NGC 5548 warm absorber are a factor of ~ 10 larger. A similar trend is found for NGC 4051 ($\alpha \sim 0.5$ Ogle et al. 2004), with an apparent peak for $N_{\rm H}$ at $\log \xi = 1.4$. We note however that this result is not completely comparable to Mrk 279 and NGC 5548 as Ogle et al. (2004) compute $\log \xi$ at the peak of the ionization for each ion. Not taking into account that ions are formed in a range of $\log \xi$ can lead to a quite different distribution. Finally, in the case of Mrk 279, the extrapolation of the $\log \xi > 0$ power law to lower ionization ions, excludes the lowest ionization ions from the continuous outflow structure, consistent with the idea that those ions are produced in a distant region.

An additional constraint is provided by the WARM model fit (Fig. 10). The hydrogen column densities from the WARM model have more robust values, as the SPEX fit synthetically takes into account all transitions for a given value of the ionization parameter. The WARM distribution does not suggest a straight power law fit. However, the power law fit to the single ions distribution ($\alpha \sim 0.49$) nicely adapts to the $\log \xi$ =0.4 and 3.2 points at which the $N_{\rm H}$ was evaluated in the WARM model (Sect. 2.4.2). If we take this as the signature of a continuous distribution, both the lower ionization end of this distribution ($\log \xi < -1$) and the point evaluated at $\log \xi = 1.8$ deviate from the power law distribution (with 4σ significance). In the framework of the structure of the ionized outflow, we are mostly interested in the apparent dip in this continuous distribution at $\log \xi = 1.8$. We further verified that fitting the data with

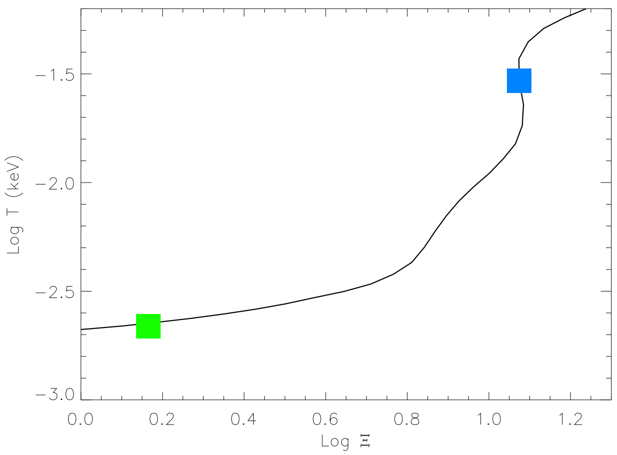

Fig. 12. The pressure ionization parameter *vs* the electron temperature. The two components of the warm absorber for Mrk 279 are indicated as squares.

an additional XABS components with $\log\xi$ constraint to lie between 0.47 and 2.49 (values from the XABS best fit, see Tab. 7) does not significantly change the goodness of fit in terms of χ^2, but indeed provides a lower and significant value for $N_{\rm H}$. We find $\log\xi = 1.5^{+0.3}_{-0.2}$ and $N_{\rm H} = 2.8 \pm 0.4 \times 10^{19}$ cm^{-2}.

The main point that may be deduced from this exercise is that the continuous distribution we tried to define is in fact non-monotonous. We do not find a sharp bimodal distribution with $\log\xi \sim 0.47$ and $\log\xi \sim 2.49$ being the only components of the warm absorber (as suggested by the XABS model, Sect. 2.4.1). Intermediate values may exist, but with a column density that is low enough not to be easily detected. This is in contrast with what is predicted by a power law distribution fit. The statistics does not allow us to detail further these findings. For instance the kinematic characteristics of this outflow are not precisely determined: the blue-shifts of the two ionization components we find are only marginally different (Tab. 7). The kinematic warm absorber structure for Mrk 279 is indeed quite complex. A velocity-resolved spectroscopy of the UV absorption troughs of this source shows that not only partial covering plays a role (Arav et al. 2005, Sect. 2.4), but that abundances of C, N, and O can differ from solar values (Arav et al. 2006, in prep.). The N/O and C/O ratio delivered by the X-ray data are affected by large error bars, therefore a direct comparison with the UV results is not conclusive.

3.3. Density diagnostics

Kaastra et al. (2004) discussed in detail the possibility of the detection of O V absorption lines from a meta-stable level in Mrk 279. The main absorption feature (O V*) lies at ~ 22.5 Å in the rest frame of the source (23.18 Å in the observed spectrum, Fig. 8). This kind of transition of Be-like ions can take place only at particularly high densities. Therefore, a precise determination of the physical parameters of such absorption features can serve as an important test for the distance determination of the warm absorber. Here we try to verify a connection between the parameters deduced from the O V* line and any of the absorber components in Mrk 279.

The temperatures Kaastra et al. (2004) infer for the gas producing the O V* line range between $2-4$ eV, corresponding, for the SED of Mrk 279, to $\log\xi \sim 0-1.5$. This estimate of the ionization parameter, together with the hydrogen column density ($N_{\rm H}$) that we can derive from the equivalent width of the O V ground state absorption lines ($N_{\rm OV} = 1.4^{+0.5}_{-1} \times 10^{16}$ cm^{-2}, Kaastra et al. 2004), give already the basic physical quantities of a warm absorber. In order to ensure that the density value of a gas producing O V* is not unrealistic, we find that a gas temperature kT <3 eV is needed. For this temperature, the O V/O ratio is 0.02, implying an equivalent hydrogen column density $N_{\rm H} \sim 8 \times 10^{20}$ cm^{-2}, which is still roughly compatible with the column density we find for a continuous-distribution warm absorber model (Fig. 10) . The associated ionization parameter would be $\log\xi \sim 1$. The comparison between the temperature of this gas (~ 3 eV) and the measured relative population of the O V metastable levels (0.125–2, Kaastra et al. 2004), provides an estimate for the density (see Fig. 5, Kaastra et al. 2004). We obtain $n > 3 \times 10^{12}$cm^{-3} and, as a consequence, a distance from the ionizing source $r_0 < 3 \times 10^{15}$ cm, comparable with the location of a more ionized part of the BLR. This estimate relies uniquely on the tentative detection of O V*. Further observational evidence is needed to support the identification of this line.

3.4. The emission counterpart of the warm absorber

Whether the gas which is responsible for the blue-shifted absorption lines is also observed in emission, is a controversial issue. The main reason is that the absorption/emission connection is dependent on unknown parameters, such as the density, the distance, and the overall geometry of the system. The emission counterpart of the X-ray warm absorber may be the narrow lines produced in the NLR in a form of a bipolar cone with a wide opening angle (e.g., NGC 3783, Behar et al. 2003). The observational facts that would support this scenario are: a lack of response of the warm absorber to the central source variability and the similarity of the absorption and emission lines parameters, such as velocity width, column density, ionization stage. In the case of Mrk 279, any suggestion of a short-term variation of the absorber parameters as a function of the ionizing flux is unfortunately too weak ($\sigma < 2$) to be investigated quantitatively. Narrow emission lines are not affecting the spectrum significantly. From the study of the possible O V* feature (Sect.3.3, Kaastra et al. 2004), we inferred an upper limit for the distance of the warm absorber ($r_0 < 3 \times 10^{15}$cm), at least for an intermediate ionization component. The emission counterpart of the X-ray warm absorber would be located at the same distance as the higher ionization BLR lines (i.e. the X-ray lines, Sect. 3.1). Can the BLR cloud themselves produce the warm absorber? The particular blue-shift seen in the absorption feature can be line-of-sight dependent (Elvis 2000), while the broad lines can be emitted over a maximal opening angle of 2π. The UV broad lines are consistent to have a variety of velocity including extreme blue-shifted components of $\sim$-2000 km s^{-1} (G05). Moreover the absorbing and emitting gas can have the same structure, as the BLR "clouds" can be organized in the form of a wind arising above the accretion disk (e.g., Bottorff et al. 1997) just like the warm absorber (e.g., Elvis 2000). However, one insurmountable discrepancy between the two media is the measured column density. Indeed, the UV (and X-ray) broad emission lines can be produced for column densities down to $N_{\rm H} \sim 10^{22}\,{\rm cm}^{-2}$ (Korista et al. 1997), which is almost two orders of magnitude higher than the warm absorber of Mrk 279. Furthermore, the evidence of narrow absorption lines ($\sigma \sim 50\,{\rm km\,s}^{-1}$) point to a stable flow. This would be difficult to maintain in a turbulent medium like the one producing the BLR. The possibility that the broad emission lines are produced by the same gas component as the warm absorber is then ruled out. However, in a picture of a windy gas above the accretion disk, our line sight may intercept first a portion of the absorber very close to the central source. Its transverse thickness must be very small ($N_{\rm H}/n_{\rm H} \approx 10^{5-6}$ cm). This sheet of gas may be the outer, low column density part of the gas structure that produces the broad emission. If the limit on the distance of the absorber is confirmed (Sect. 3.3), this could be a way to make the two media coexist at approximately the same distance from the central source. A correspondence between the distance of the warm absorber and the BLR was also found in other X-ray sources (e.g. NGC 3516, Netzer et al. 2002). A physical connection between the BLR and the warm absorber was proposed for NGC 3783, observed by *Chandra*-HETGS (Krongold et al. 2003). Finally, the gas temperature inferred from the RRCs fit translates in an ionization parameter, $\log\xi$, from –1.3 to 0.8, which is certainly consistent with the $\log\xi$ of one of the main absorbing components of the warm absorber in Mrk 279. Therefore, a physical link between the warm absorber and the gas producing the RRCs cannot be ruled out.

4. Conclusions

We have presented the analysis and modeling of the data of Mrk 279, observed for 360 ks by *Chandra*-LETGS. For the first time, we have extended to the X-ray band the "locally optimally cloud" model, first proposed by Baldwin et al. (1995) to describe the BLR emission lines seen in the UV. This has been achieved by fitting first the luminosity of the UV lines, measured simultaneously by FUSE and HST-STIS (G05) and deriving, from the best fit, the X-ray luminosity.

In agreement with the LOC model predictions, the distribution of the radial distance of the BLR "clouds" follow a power law with index $\gamma = -1.02 \pm 0.14$, assuming a density distribution with index $\beta = -1$. We find that the inferred X-ray line luminosity well describe the X-ray spectral shape. If, independently, we fit the X-ray broad emission features with Gaussian profiles, the results are, within the errors, consistent with the UV modeling. The most evident X-ray broad emission feature, the O VII triplet, which exceeds the continuum of about 30%, is well explained by the LOC model. The profiles of other important X-ray lines of the H-like and He-like C, N, O ions are less clear in the spectrum and cannot be studied in more detail. It would be important to quantitatively measure the contribution of such ions, as they may be more sensitive to the physical conditions than O VII, which is steadily produced for a wide range of gas densities and distances from the ionizing source. There are not significant spectral residuals in excesses after the inclusion of the X-ray broad lines. This suggests first that the gas of the BLR emitting the bulk of the UV emission is also sufficient to explain the X-ray emission spectrum. Second, that the contribution of lines arising instead from the innermost region of the accretion disks, and thus relativistically broadened, is negligible in the case of Mrk 279.

In the radial distribution of the line luminosity, the luminosity–weighted radius for each ion considered defines a wide region of roughly 90 ld for the UV–X-ray BLR (67 ld if only the UV ions are considered). This is larger than predicted by reverberation mapping studies (Stirpe et al. 1994). However, our estimate could be lowered by a factor up to three noting that the BLR size is sensitive to the long term variations of the continuum flux and that at the epoch of the present campaign the optical flux was at the higher end of a gradual rise that lasted nearly two months.

A proper modeling of the broad emission lines in the LETGS spectrum helps in the analysis of the absorbed spectrum. We find the signature of at least two gas components which can be unmistakably associated with a warm absorber. However, there is some evidence that suggests that this may be only a partial description of the absorption. First, absorption lines do not show any significant variation following the modest changes of the central source flux and, second, the two absorption components cannot be in pressure equilibrium. This evidence, although not decisive, does not strongly support the hypothesis of a compact absorber (Krongold et al. 2005). We investigated the possibility that the absorbing gas is instead distributed over a wide range of ionization parameters (Steenbrugge et al. 2005). We find that neither of the two models perfectly matches our data. A smooth distribution of the column densities is accepted, but $N_{\rm H}$ does not monotonically increase as a function of ξ (following for example a power law), but it is rather significantly bent.

From the exploratory study of the possible O V absorption line to meta-stable level in the Mrk 279 X-ray spectrum, Kaastra et al. (2004) infer a density for the absorbing gas of the order of $10^{14}\,{\rm cm}^{-3}$. In the context of our analysis, we find that an intermediate ionization gas component ($\log\xi \sim 1$), with a column density roughly consistent with our continuous-distribution model, could be consistent to produce the O V* line. This would imply an upper limit to the distance from the central source of 3×10^{15} cm for the gas. Although a distance close to the BL emitting region for the warm absorber is not new in the literature (e.g., Nicastro et al. 1999; Netzer et al. 2002), in the case of Mrk 279, a global model explaining the coexistence of the complex warm absorber structure and the BLR cannot be easily depicted.
